Human infections with the emerging avian influenza A H7N9 virus from wet market poultry: clinical analysis and characterisation of viral genome

Yu Chen*, Weifeng Liang*, Shigsui Yang*, Nanping Wu*, Hainv Gao, Jifang Sheng, Hangqiang Yao, Jianer Wo, Qiang Fang, Dawei Cui, Yongcheng Li, Xing Yao, Yuntao Zhang, Haibo Wu, Shufa Zheng, Hongyan Diao, Shichang Xia, Yanjun Zhang, Kwok-Hung Chan, Ho-Wah Tsai, Jade Lee-Lee Teng, Wenjun Song, Pui Wang, Siu-Ying Lau, Min Zheng, Jasper Fuk-Woo Chan, Kelvin Kai-Wang To, Honglin Chen, Lanjuan Li, Kwok-Yung Yuen

Summary

Background Human infection with avian influenza A H7N9 virus emerged in eastern China in February, 2013, and has been associated with exposure to poultry. We report the clinical and microbiological features of patients infected with influenza A H7N9 virus and compare genomic features of the human virus with those of the virus in market poultry in Zhejiang, China.

Methods Between March 7 and April 8, 2013, we included hospital inpatients if they had new-onset respiratory symptoms, unexplained radiographic infiltrate, and laboratory-confirmed H7N9 virus infection. We recorded histories and results of haematological, biochemical, radiological, and microbiological investigations. We took throat and sputum samples, used RT-PCR to detect M, H7, and N9 genes, and cultured samples in Madin-Darby canine kidney cells. We tested for co-infections and monitored serum concentrations of six cytokines and chemokines. We collected cloacal swabs from 86 birds from epidemiologically linked wet markets and inoculated embryonated chicken eggs with the samples. We identified and subtyped isolates by RT-PCR sequencing. RNA extraction, complementary DNA synthesis, and PCR sequencing were done for one human and one chicken isolate. We characterised and phylogenetically analysed the eight gene segments of the viruses in the patient’s and the chicken’s isolates, and constructed phylogenetic trees of H, N, PB2, and NS genes.

Findings We identified four patients (mean age 56 years), all of whom had contact with poultry 3–8 days before disease onset. They presented with fever and rapidly progressive pneumonia that did not respond to antibiotics. Patients were leucopenic and lymphopenic, and had impaired liver or renal function, substantially increased serum cytokine or chemokine concentrations, and disseminated intravascular coagulation with disease progression. Two patients died. Sputum specimens were more likely to test positive for the H7N9 virus than were samples from throat swabs. The viral isolate from the patient was closely similar to that from an epidemiologically linked market chicken. All viral gene segments were of avian origin. The H7 of the isolated viruses was closest to that of the H7N3 virus from domestic ducks in Zhejiang, whereas the N9 was closest to that of the wild bird H7N9 virus in South Korea. We noted Gln226Leu and Gly186Val substitutions in human virus H7 (associated with increased affinity for α-2,6-linked sialic acid receptors) and the PB2 Asp701Asn mutation (associated with mammalian adaptation). Ser31Asn mutation, which is associated with adamantane resistance, was noted in viral M2.

Interpretation Cross species poultry-to-person transmission of this new reassortant H7N9 virus is associated with severe pneumonia and multorgan dysfunction in human beings. Monitoring of the viral evolution and further study of disease pathogenesis will improve disease management, epidemic control, and pandemic preparedness.

Funding Larry Chi-Kin Yung, National Key Program for Infectious Diseases of China.

Introduction Influenza A virus is subtyped on the basis of two surface proteins, haemagglutinin (H) and neuraminidase (N), which govern the viral lifecycle at cellular entry and release of virions. All subtypes of influenza A virus, from H1 to H16 and N1 to N9, are detected in wild water birds; H7N10 is found in bats.1 Although most infections with these subtypes are mild or asymptomatic in avian species, outbreaks in wild birds and poultry have been associated with highly pathogenic avian influenza H5, and outbreaks in poultry have been associated with H7 subtypes.23 Human infections are generally confined to H1, H2, and H3 subtypes, because these subtypes have affinity for host cell receptors containing α-2,6-linked sialic acid (which occur in human beings), whereas other avian influenza viruses generally preferentially attach to avian host cell receptors, which contain α-2,3-linked sialic acid. Direct transmission of avian influenza viruses from domestic poultry to people have been documented only for the H5N1, H7N2, H7N3, H7N7, H9N2, and H10N7 subtypes.23,4 Human infections due to these subtypes were generally mild and manifested as conjunctivitis and upper-respiratory-tract infections, except for the...
H5N1 subtype, which was associated with mortality of greater than 50%, and the H7N7 subtype, which has caused one death.\(^1\)\(^2\) Since February, 2013, a novel reassortant H7N9 virus associated with human deaths but no apparent outbreaks in poultry and wild birds has emerged in eastern China. We report on four patients with severe infection due to this H7N9 virus. We sequenced, characterised, and compared viral genomes from a patient and an epidemiologically linked wet market chicken isolate.

\(+\) indicates the presence of a symptom, and \(-\) the absence. APACHE=acute physiology and chronic health evaluation. NA=not applicable. *The presumed incubation period is defined as the time between the last exposure to poultry and onset of symptoms.
review board of the First Affiliated Hospital, College of Medicine, Zhejiang University (reference number 2013-131). We entered history; physical examination; and haematological, biochemical, radiological, and microbiological investigation results into a predesigned database. We recorded patients’ acute physiology and chronic health evaluation II (APACHE-II) scores and defined acute respiratory distress syndrome and multiorgan dysfunction syndrome on the basis of standard criteria. Presumed incubation period was defined as the time between last poultry exposure and onset of symptoms.

All laboratory procedures for respiratory secretions have been previously reported. Briefly, we used Taqman real-time RT-PCR under standard thermocycling conditions to detect M, H7, and N9 genes. The primers that we used were M-forward (GAGTGGCTAAAGACAAGACCAATC), M-reverse (TTGGACAAAGCGTCTACGC), and M-probe (FAM-TCACCGTGCCAGTGAGCGAG-BHQ1); H7-forward (AGAGTCATTARAAATGAATACAGAT), H7-reverse (CACGCGATGTGGATCCCATGCTTTTTTC), and H7-probe (FAM-AAACATGGCGGCAGGCTCAAAAC-BHQ1); and N9-forward (GTTCTATGCTCTCAGCCAAGG), N9-reverse (CTTGACCACCAATGCCCCG), and N9-probe (HEX-TAAGCTRCCACTATCATCACCCRC-BHQ1). The detection limit of the M, H7 and N9 RT-PCR assays was about 100 copies of RNA per mL. All samples were cultured with trypsin in the Madin-Darby canine kidney cell line for 7 days. We did immunofluorescent antigen staining for influenza A nucleoprotein (D3 ultra 8 DFA, respiratory virus screening and identification kit, Diagnostic Hybrid, OH, USA) under ultraviolet microscopy (Eurostar III plus, Euroimmun AG, Lubeck, Germany) in cell cultures with positive cytopathic changes. RT-PCR was used to subtype for H1, H3, H5, H9, and H7.

We assessed patients’ respiratory tract samples on admission by multiplex PCR (Luminex 200 System, Luminex, TX, USA); did ResPlex II v2.0 assays (Qiagen, Germany) to detect co-infection with respiratory syncytial virus, influenza B virus, parainfluenza viruses 1–4, human metapneumovirus, enteroviruses, rhinovirus, adenovirus, bocavirus, and coronavirus NL63, HKU1, 229E, and OC43; and used PCR to detect coinfection with Mycoplasma pneumoniae and Chlamydophila pneumoniae. We investigated blood, sputum, or endotracheal aspirates and urine samples bacteriologically, as clinically indicated. Initial urine samples were tested for pneumococcal and Legionella antigens by immunochromatographic enzyme immunoassay (Binax NOW Streptococcus pneumoniae Urinary Antigen Test and Binax NOW Legionella Urinary Antigen Test, Binax, ME, USA). We used the Luminex enzyme immunoassay (Luminex, TX, USA) to monitor six different serum cytokines or chemokines—namely, interferon γ, interleukins 2, 4, 6, and 10, and tumour necrosis factor α (TNFα)—as a measure of host immunological responses.

Procedures in poultry and genome characterisation

Cloacal swabs were collected from 20 chickens, four quails, five pigeons, and 57 ducks from six epidemiologically linked wet markets (four in Hanzhou City and two in Huzhou City, Zhejiang) and stored in viral transport medium. The collected samples were inoculated into embryonated chicken eggs and viral replication was detected by haemadsorption, which was previously described. We identified and subtyped isolates by RT-PCR sequencing (we used H7-specific and N9-specific primers). RNA extraction, complementary DNA synthesis, and PCR sequencing were done for one human and one chicken isolate. Sequencing was done with the BigDye Terminator v3.1 Cycle Sequencing Kit on the 3130xL Genetic Analyzer.

Figure 1: Representative radiographic findings of H7N9 influenza

Chest radiograph of patient 1 taken 19 days after onset of symptoms, showing bilateral pulmonary infiltrates of airspace consolidation (A); CT of patient 1 taken 13 days after onset of symptoms, showing consolidation of right middle lobe (B); chest radiograph of patient 2 taken 14 days after onset of symptoms, showing bilateral interstitial infiltrate (C), and serial CTs of patient 4 taken 20 (D), 27 (E), and 35 (F) days after onset of symptoms, showing interval radiological improvement and resolution of bilateral ground glass changes.
Articles

(Applied Biosystems, NY, USA). We characterised and phylogenetically analysed all eight gene segments of the patient’s and the chicken’s isolates together with virus sequence data available from GenBank. All sequences were assembled and edited with Lasergene 6.0 (DNASTAR, WN, USA); Bioedit 7 was used for alignment and analysis of aminoacid residues. We used the MEGA software package v5.05 (Center for Evolutionary Medicine and Informatics, Biodesign Institute, AZ, USA) to construct the phylogenetic trees of H, N, PB2, and NS genes on the basis of the neighbour-joining method, with Tamura-Nei model of nucleotide substitution. The nucleotide of the HA1 region was used for analysis. Bootstrap values from 1000 replicates were calculated to assess the reliability of the phylogenetic tree. Our gene sequences are deposited in GenBank (accession numbers KC885955-62 [human isolate], KC899666-73 [chicken isolate]).

Role of the funding source
The sponsors had no role in study design; data collection, analysis, or interpretation; or writing of the report. The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Results
All four patients had history of poultry contact (table 1). The presumed incubation period ranged from 3 to 8 days (mean 5·8 days). Mean age was 56 years (table 1). None of the patients were obese and none had upper-respiratory-tract symptoms or conjunctivitis. All patients had fever, and lower-respiratory-tract symptoms (including dyspnoea, cough, and sputum), and one had prominent myalgia (table 1). Chest radiography and CT of all patients showed multilobar patchy consolidation and diffuse alveolar opacities (figure 1A–1F). CT of patients 1 and 4 showed ground glass changes in some areas. Mean time between onset of symptoms and respiratory failure was 9 days.

Three patients were given 75 mg oral oseltamivir twice daily after tests for H7N9 virus were positive, starting a mean of 16 days after onset of symptoms onset (table 1). All patients required respiratory support—oxygen given through nasal cannulae at presentation. Two patients needed non-invasive ventilation by continuous positive airway pressure, and three subsequently received mechanical ventilation. Two patients received intravenous immunoglobulin and all received intravenous methylprednisolone (table 1). Two patients (patients 1 and 3) died 4 days after intubation. The other two patients were recovering clinically and radiologically and had been successfully extubated at the time of writing (figure 1). 303 household or workplace contacts and 82 health-care workers with unprotected exposure to the four patients were put under medical surveillance but none of them became symptomatic after 14 days.

Table 2 lists the results of laboratory investigations in the patients. All patients had pronounced lymphopenia at presentation. Total leucocyte counts were healthy or low at presentation, but leucocytosis with neutrophilia developed with disease progression. Three patients had thrombocytopenia at presentation. The nucleotide of the HA1 region was used for analysis. Bootstrap values from 1000 replicates were calculated to assess the reliability of the phylogenetic tree. Our gene sequences are deposited in GenBank (accession numbers KC885955-62 [human isolate], KC899666-73 [chicken isolate]).

D-dimer concentrations. Hepatic aminotransferases, C-reactive protein, and creatine kinase or lactate dehydrogenase concentrations were increased in all patients at some stage of illness; derangement was worse in those who died.

Overall, serum cytokine and chemokine concentrations were substantially higher in patient 3 (who died) than in patient 2 (who survived) (figure 2A, 2B). Patient 3 had persistently high serum interleukin 10 concentrations (figure 2B) before death. RT-PCR assays of throat swab samples or sputum samples yielded positive results for H7N9 infection in all patients (table 3). Serial samples from patient 2 were tested; throat swab samples were consistently negative, but sputum samples were positive (table 3). H7N9 virus was isolated from respiratory specimens from patients 1, 3, and 4 in cell culture, and confirmed by RT-PCR (in which H7-specific and N9-specific primers were used). No viral co-infections were detected by multiplex PCR, and no bacterial or fungal co-infections were detected in 14 blood cultures and 16 respiratory secretion cultures. Two of five pigeons (40%), four of 20 chickens (20%), zero of four quails (0%), and zero of 57 ducks (0%) tested positive for the H7N9 virus.

Sequence analysis of patient 3 and an epidemiologically linked chicken’s H (1673 of 1683 bases [99·4%]) and N (1394 of 1398 bases [99·7%]) genes showed that the human H7N9 isolate was almost identical to chicken H7N9 isolate. The H7 in the isolates clustered with H of the H7N3 of ducks in Zhejiang, and the isolate N9 clustered with the N of the H7N9 of wild birds in Korea (figure 3). The six internal genes of the isolate H7N9 are closest to those of poultry H9N2 viruses of China (figure 4).

Analysis of the H7 receptor binding site showed a Gln226Leu substitution in the human isolate and a Gly186Val substitution (H3 numbering) in both human and chicken isolates (table 4). No multibasic aminoacids were noted at the proteolytic cleavage site of this H7 in either the human or the chicken isolates. Although the PB2 Glu627Lys substitution frequently detected in human H5N1 isolates was not noted, an Asp701Asn substitution was noted in the human isolate. Deletion of five aminoacids in the stalk region of N9 at position 69–73 (N9 numbering) was noted in the human and chicken H7N9 isolates. We detected a premature stop codon near the C-terminus of NS1, leading to PDZ motif deletion, in all H7N9 isolates. A Ser31Asn substitution of the M2 gene associated with adamantane resistance was recorded in both isolates, but we noted no resistance mutations associated with neuraminidase inhibitors.

Discussion
We diagnosed avian influenza A H7N9 in all four patients (who were epidemiologically unlinked), two of whom died and two of whom were recovering at the time of writing (panel). All patients had histories of occupational or wet market exposure to poultry. The genes of the H7N9 virus in patient 3’s isolate were phylogenetically clustered with those of the epidemiologically linked wet market chicken H7N9 isolate. Human and chicken isolate H7 clustered with that of H7N3 of ducks in Zhejiang, and human and chicken isolate N9 clustered with that of H7N9 of wild birds in Korea, and the six internal genes of the isolate H7N9 are closest to those of poultry H9N2 viruses of China. These findings suggest sporadic poultry-to-person transmission.

As was the case with influenza A H5N1 virus in 1997, severe acute respiratory syndrome (SARS) coronavirus
in 2003, and human coronavirus EMC in 2012, infection with a novel virus was suspected because the pneumonia of these patients did not respond to typical and atypical antibiotic coverage. The four patients were clustered within Zhejiang, China, within a few weeks (when migratory birds were moving north and transiting

Table 3: Virological findings in patients with avian influenza A H7N9 virus infection

Figure 3: Phylogenetic trees for the haemagglutinin (HA1) (A) and neuraminidase (N) (B) genes of H7N9 viruses isolated from a patient and a chicken in Zhejiang, China

Sequences of H7N9 viruses characterised in our study are red—A/Zhejiang/UTID-ZJU01/2013 (H7N9) is the human isolate and A/chicken/Zhejiang/UTID-ZJU01/2013 (H7N9) is the epidemiologically linked chicken isolate. H7N7 viruses that were reported to cause human infections are blue. Human isolates of H7N9 viruses described in a 2013 report are green. The other sequences (black) were derived from other subtypes of influenza viruses that were available in Genbank. The triangle represents viruses of North American (ie, Canadian, Mexican, and US) lineage.
at the Yangtze River Delta). However, unlike other types of avian influenza affecting human beings, no increase in poultry deaths was noticed before the onset of human infections. After diagnosis of influenza A H7N9 infection was confirmed in patient 1 by RT-PCR, additional and retrospective testing of 486 patients between March 7 and April 8, 2013, led to the discovery of three further infected patients.

Similar to those infected with H5N1, our patients had few upper-respiratory-tract symptoms. They presented with high fevers, lower-respiratory-tract symptoms (especially dyspnoea), and radiological features of consolidation and ground glass changes. Multiorgan involvement was shown by abnormal results of liver and renal function tests, myalgia (with high creatine kinase concentrations suggestive of myositis), impaired coagulation, and severe lymphopenia. Gastrointestinal symptoms were noted only suggestive of myositis), impaired coagulation, and severe lymphopenia. Gastrointestinal symptoms were noted only suggestive of myositis), impaired coagulation, and severe lymphopenia. Gastrointestinal symptoms were noted only suggestive of myositis), impaired coagulation, and severe lymphopenia. Gastrointestinal symptoms were noted only suggestive of myositis), impaired coagulation, and severe lymphopenia.

Besides the likely absence of protection by pre-existing neutralising antibodies in the general population, the internal genes from the H9N2 virus might also contribute to the severe pathogenesis of this novel infection. Double and even triple reassortant avian H9N2 viruses were well reported, and the six internal genes of the 1997 H5N1 virus originated from avian H9N2 virus. Furthermore, H9N2 and H5N1 viruses both induced prominent cytokine and chemokine activation in human macrophages and epithelial cells compared with that induced by seasonal influenza A H1N1 virus. In previous studies, treatment with convalescent plasma or hyperimmune y globulin seemed to improve survival of patients and therefore hyperimmune y globulin should be considered in the treatment of severe H7N9 infection.
(but not corticosteroids) improve outcomes of H5N1 infections in mice.22

Other host factors, such as smoking and obesity, are risk factors for severe influenza.22-23 Findings from murine models challenged with influenza viruses sug- gestion that smoking worsens the response of proinflam-

matory chemokine and cytokines and histological

changes of inflammatory infiltrates and lung damage,

increases viral titres, and impairs pulmonary adaptive T-lymphocyte responses to the virus.23

Rapid virological diagnosis was established by RT-PCR of the M, H7, and N9 genes and confirmed by viral
culture in cell lines. Similar to H5N1 infection, which
mainly affected the lower respiratory tract, sputum and
endotracheal aspirates might be better than nasopa-

thineural markers of mammalian adaptation were found
in the human virus isolate. Clinical manifestation of this new
emerging infection is similar to that of H5N1 infection and can
be fatal in patients with substantial cytokine activation and
multiorgan dysfunction. Further virological study is important
to establish diagnosis and allow early treatment with
neuraminidase inhibitors and infection control. Rising poultry
and human populations will increase the emergence of novel
avian influenza viruses infecting human beings.

### Panel: Research in context

#### Systematic review

We searched PubMed on April 11, 2013, with the terms “influenza”, “avian”, “H5”, “H5N1”, “H7”, “H9”, and “H10” for articles published in English. Our search did not reveal any reports of avian influenza A H7N9 virus infection in human beings before 2013. We noted only reports of poultry outbreaks caused by some H7N9 virus strains, which were usually weakly pathogenic for avian species. All reported human infections with avian influenza A virus were caused by
H5N1, H7N2, H7N3, H7N7, H9N2, and H10N7 subtypes. Severe community-acquired pneumonia and multiorgan dysfunction due to H5N1 infection was associated with a mortality rate of more than 50%, and one death due to the H7N7 subtype has been reported.4 However, most H7 viruses and other subtypes caused mild respiratory illness or conjunctivitis in people. Most cases were attributed to avian-to-human transmission, and there was little evidence of first generation person-to-person transmission.

#### Interpretation

Our study showed that human infections with the avian influenza A H7N9 virus were acquired from live poultry markets in China (evidenced by the phylogenetic relatedness between viruses in isolates from a patient and an epidemiologically linked chicken). Markers of mammalian adaptation were found in the human virus isolate. Clinical manifestation of this new emerging infection is similar to that of H5N1 infection and can be fatal in patients with substantial cytokine activation and multiorgan dysfunction. Further virological study is important to establish diagnosis and allow early treatment with neuraminidase inhibitors and infection control. Rising poultry and human populations will increase the emergence of novel avian influenza viruses infecting human beings.

efficient person-to-person transmission. Sequence analysis showed that the human H7 had aminoacid substitutions associated with increased affinity for the human α-2,6-linked sialic acid receptor. However, binding to the α-2,3-linked sialic acid receptor is likely to be retained, allowing the virus to circulate in poultry and infect human lower-respiratory-tract mucosae, which contain both types of receptor.

Shortening of the N stalk region of H5N1 viruses enhanced adaptation to land-based poultry. An important virus protein, PB2, in combination with two other viral proteins, PB1 and PA, comprise the viral RNA polymerase complex. PB2 is an important determinant of the host range and virulence of influenza viruses. Two aminoacids in PB2, 627Lys and 701Asn, have previously been detected in H5N1 viruses isolated from people. Aminoacid motif associated with virulence and the aminoacid substitution. Another study of the current H7N9 outbreak showed that the human H7 had aminoacid substitution—ie, Gln226Leu and Asp701Asn—in the chicken isolate, which suggests that this genetic adaptation might have occurred after the virus jumped from the chicken to the patient. Ser31Asn mutation (associated with adamantane resistance) was noted, but neuraminidase inhibitors, including oseltamivir, zanamivir, and peramivir, should still be active if given early in the course of illness. One patient did not receive any antivirals and three patients received oseltamivir more than 5 days after onset of symptoms. We do not know whether oseltamivir resistance will emerge (as was the case with the H5N1 virus) because the last H7N9-positive sample from patient 2 was not tested for oseltamivir resistance after 5 days of oseltamivir treatment. Delayed initiation of oseltamivir treatment and use of corticosteroids have been associated with slow decreases in viral load and poor outcomes.

In 2003, an H7N7 virus, which contained the multibasic aminoacid motif associated with virulence and the genetic marker for mammalian adaptation (Glu627Lys) caused one fatal infection in the Netherlands. Other severe human infections with the H7 subtype had not been reported before the current H7N9 outbreak. Previous surveillance studies have shown the H7N3 virus to be present in domestic ducks in Zhejiang. Avian H7 subtype viruses are likely to have become established in domestic poultry in Zhejiang. Interaction between newly established H7 subtypes and other avian influenza viruses, such as the H9N2 subtype, might have resulted in the current H7N9 strain, which has gained some ability to infect human beings. Further adaptation could lead to less symptomatic infection and more efficient person-to-person transmission. Aggressive intervention to block further animal-to-person transmission in live poultry markets, as has previously been done in Hong Kong, should be considered. Temporary closure of live bird markets and comprehensive programmes of surveillance, culling, improved biosecurity, segregation of different poultry species, and possibly vaccination programmes to control H7N9 virus infection in poultry seem necessary to halt evolution of the virus into a pandemic agent.

Contributors
LL and K-YY were coprincipal investigators, designed and supervised the study, and wrote the grant application (assisted by YC), WL, SY, HG, JS, QF, YL, YX, YZ, and SX had roles in recruitment, data collection, and clinical management. NW, HY, JW, DC, HW, SZ, HD, YZL, K-HC, H-WT, and JL-LT did clinical laboratory testing and analysis. WS, PW, SYL, MZ, and HC did the genome sequencing and analysis. JW, WC, KKWT, HC, K-YY, and LL drafted the Article, and all authors contributed to review and revision and have seen and approved the final version.

Conflicts of interest
We declare that we have no conflicts of interest.

Acknowledgments
A donation from Larry Chi-Kin Yung and the National Key Program for Infectious Diseases of China (2012ZX10004210) funded the manpower and laboratory testing for this study. HC is partly supported by the Areas of Excellence of the University Grants Committee (Grant AoE/M-12/06). K-YY is partly supported by the Consultancy Service for Enhancing Laboratory Surveillance of Emerging Infectious Disease of the Department of Health, Hong Kong Special Administrative Region, China. We acknowledge the contributions of Lingxiang Ruan, Qi’bing Pu, Zhiping Chen, the technical staff of the Department of Microbiology at the University of Hong Kong, and Yuelong Shu for permitting us to use the data he deposited in Global Initiative on Sharing All Influenza Data (GISAID) EpiFlu.
